Abstract: Several studies have shown that the Dempster–Shafer theory (DST) can be successfully applied to scenarios where model interpretability is essential. Although DST-based algorithms offer significant benefits, they do face challenges in terms of efficiency. We present a method for the Dempster–Shafer Gradient Descent (DSGD) algorithm that significantly reduces training time—by a factor of 1.6—and also reduces the uncertainty of each rule (a condition on features leading to a class label) by a factor of 2.1, while preserving accuracy comparable to other statistical classification techniques. Our main contribution is the introduction of a “confidence” level for each rule. Initially, we define the “representativeness” of a data point as the distance from its class’s center. Afterward, each rule’s *confidence* is calculated based on *representativeness* of data points it covers. This confidence is incorporated into the initialization of the corresponding Mass Assignment Function (MAF), providing a better starting point for the DSGD’s optimizer and enabling faster, more effective convergence. The code is available at <https://github.com/HaykTarkhanyan/DSGD-Enhanced>.

Categories: I.2.6, I.5, G.3

1 Introduction

Dempster–Shafer theory [Shafer 1976] has emerged as a powerful framework for developing classification algorithms that prioritize interpretability. This theory provides a mathematical approach for combining evidence from different sources to calculate the probability of an event, utilizing Dempster’s rule of combination. Peñafiel et al. [Peñafiel et al. 2020] have demonstrated for classification tasks that an algorithm combining Dempster–Shafer theory with optimization techniques can offer substantial explainability, even when employing a limited number of rules, without sacrificing accuracy. The algorithm was further extended to the regression case by Baloian et al. [Baloian et al. 2024] and to clustering by Valdivia et al. [Valdivia et al. 2024]. The algorithm is inherently explainable because it operates by combining relatively simple rules for inference. Additionally, recent work by Baloyan et al [Baloyan et al. 2024] demonstrates algorithm’s robustness to class imbalance and its ability to capture various numeric interactions among features.

To make improvements, two issues should be considered. Firstly, the number of subsets in the frame of discernment, growing with a complexity of $\mathcal{O}(2^n)$, makes the inclusion of non-singleton classes nearly impossible. Secondly, given that each feature in the dataset typically generates three rules, combining even two rules significantly increases training time and further limits the predictive power of the rules. Moreover, one promising direction for improving DST-based methods lies in incorporating rules derived from rule mining algorithms [Cohen 1995, Salzberg 1994, Goix 2020]. However, to make this approach truly feasible, it becomes evident that a strategy to reduce training time is crucial for enhancing DST-based models.

2 Methodology

2.1 Overview

Our approach significantly reduces the optimization time by improving the technique for initializing Mass Assignment Functions associated with the rules. Peñafiel et al. [Peñafiel et al. 2020] relied on random assignment, where the empty set’s mass is set to 0, the entire set—which represents total uncertainty—is assigned a value of 0.8, and the remaining 0.2 is randomly distributed among singleton classes (other classes are not considered). Sedláček et al. [Sedláček and Bartoš 2024] have investigated the use of the statistical distribution of classes in allocating mass values. Here we propose a clustering-based technique that incorporates additional information about each rule into the Mass Assignment Function.

To advance this method, we introduce the concept of rule "confidence". First of all, operating under the assumption that certain points are more representative of their class than others we define "representativeness" for each point. This approach is inspired by the post-hoc interpretation technique commonly used in clustering algorithms. In these models, each cluster's "color" is treated as a label, upon which interpretable classifiers are constructed. In our framework, we not only assign a "color" to data points but also attribute a numeric value representing their "opacity" which we refer to as "representativeness". For spherical data, we employ the *get_representativeness_kmeans* function (see Algorithm 1), which uses the KMeans clustering algorithm [MacQueen 1967] to determine the most representative data point. In scenarios where data is better suited for density-based clustering, we apply the *get_representativeness_dbSCAN* function (see Algorithm 2, , which is based on DBSCAN [Ester et al. 1996] algorithm . Once we have determined the representativeness of each data point, we then define the confidence of each rule of the data points following that rule, this is achieved by *get_confidence* function discussed in Section 2.3. The final step involves integrating this confidence into the Mass Assignment Function (MAF) assignment, which will be discussed further in Section 2.4.

2.2 Estimation of Representativeness

Below, we present the algorithm for estimation of representativeness using KMeans clustering (Algorithm 1), while the DBSCAN-based approach (Algorithm 2) and example figures for synthetic datasets (Figure 3) are provided in the appendix.

Algorithm 1 Estimation of Representativeness using KMeans Clustering

Require: X : Dataset, k : Number of clusters (same as dataset's number of classes),
Ensure: $representativenessList$: List of representativeness values for each data point

```
1: function get_representativeness_kmeans( $X, k$ )
2:   Standardize the dataset  $X$  using standard scaling.
3:   Fit the KMeans clustering algorithm on  $X$  with  $k$  clusters to obtain centroids
    $\{C_i\}_{i=0}^{k-1}$ .
4:    $confidenceList \leftarrow$  Empty list
5:   for each  $dataPoint$  in  $X$  do
6:     Calculate Euclidean distance from  $dataPoint$  to its nearest centroid  $C_i$ .
7:   end for
8:   Identify outliers among the data points using the Z-score technique, where a data
   point is considered an outlier if its distance's Z-score exceeds  $zScoreThreshold$ .
9:   for each  $dataPoint$  in  $X$  do
10:    if  $dataPoint$  is not an outlier then
11:       $normalizedrepresentativeness \leftarrow dataPoint$ 's distance after nor-
       malizing using min-max scaling within its cluster.
12:       $representativeness \leftarrow 1 - normalizedrepresentativeness$ 
13:    else
14:       $representativeness \leftarrow 0$ 
15:      Append  $representativeness$  to  $representativenessList$ 
16:    end if
17:   end for
18:   return  $representativenessList$ 
19: end function
```

Note: The following hyperparameters are used in our approach. The first one ($zScoreThreshold$) applies to the KMeans clustering method, while the remaining three apply to the DBSCAN algorithm:

1. $zScoreThreshold = 2$
2. $minPoints = 2 \times (\text{number of features})$
3. $maxEps = 20$
4. $step = 0.05$

2.3 Rule Confidence Estimation

Utilizing the algorithms previously described, we calculate the representativeness for each data point. Afterward, we generalize this data point-specific estimate to an entire rule using the following steps (we encapsulate this in the $get_confidence$ function):

1. Filter the dataset to retain only the rows that comply with the rule.
2. If the rule does not apply to any rows, set its confidence to 0 (this corresponds to the full uncertainty). Otherwise:

-
3. Calculate the rule’s confidence as the mean representativeness of the rows it covers.
 4. If the rows are not homogeneous with respect to their labels, reduce the confidence based on the proportion of the most frequent label among these rows.

2.4 MAF Initialization

In the Mass Assignment Function (MAF), we use the following values for initialization. Let $c = \text{get_confidence}(\text{rule})$ represent the confidence derived for a given rule. The label l_{mode} , which is the most frequently occurring label within the subset of data points covered by the rule, receives the confidence value c . The remaining mass, $(1 - c)$, is evenly distributed among all the other labels present in the subset. Formally, for an element l_i in the subset:

$$m(l_i) = \begin{cases} c & \text{if } l_i = l_{\text{mode}}, \\ \frac{1-c}{n-1} & \text{otherwise,} \end{cases}$$

where $m(l_i)$ denotes the mass assigned to label l_i , and n is the total number of elements in the frame of discernment.

3 Results

Here we demonstrate the effects of the newly defined MAF initialization algorithm on the training time, accuracy, and the amount of rule uncertainties. We accomplish this by testing the approach both on controlled scenarios and on some classical datasets. The datasets used for evaluations are summarized in Table 1.

Table 1: Datasets overview (binary classification)

Dataset	Rows	Columns	Description
Brain Tumor	3762	14	Includes first-order and texture features with target levels.
Breast Cancer Wisconsin	699	9	Clinical reports detailing cell benignity or malignancy.
Gaussian	500	3	Two 2D Gaussian distributions generate this dataset.
Uniform	500	3	Uniform samples from [-5, 5], with class split by the sign of x.
Rectangle	1263	3	Points in [-1, 1] × [-1, 1], class determined by the y component’s sign.

The first two are real-life datasets ([Wolberg and Mangasarian 1990, Bohaju 2020]), while the last 3 are controlled scenarios.

3.1 Accuracy and Speedup Analysis

In this subsection, we focus on the KMeans approach, which we will refer to as the "clustering" MAF method. Additionally, we will use "MED." to denote the median and "AVG." to denote the average.

Table 2 presents a comparison of various metrics across different MAF initialization methods (Confidence and Random) and datasets. For evaluating the classifier's predictive power, we have calculated the accuracy (ratio of correctly predicted instances to the total instances) and F1 score. For evaluating the optimizer, we have reported the training time in seconds, the number of epochs, the minimum loss, and the initial loss.

Table 2: Comparison of various metrics across different MAF initializations and datasets

MAF method	dataset	accuracy	f1	training_time	epochs	min_loss	initial_loss
clustering	Brain Tumor	0.981	0.98	138.469	117	0.018	0.181
random	Brain Tumor	0.983	0.981	157.075	132	0.026	0.245
clustering	Breast Cancer	0.976	0.966	17.243	73	0.023	0.228
random	Breast Cancer	0.976	0.966	19.63	117	0.031	0.308
clustering	Gaussian	0.987	0.988	15.792	100	0.017	0.083
random	Gaussian	0.987	0.988	39.059	264	0.024	0.265
clustering	Rectangle	1	1	61.032	167	0.006	0.252
random	Rectangle	1	1	98.64	275	0.008	0.235
clustering	Uniform	0.973	0.97	20.683	120	0.035	0.197
random	Uniform	0.973	0.97	39.208	273	0.037	0.255

We can see that our method requires fewer epochs to converge in all the cases, not only that, it also starts from a better point and converges to a smaller loss.

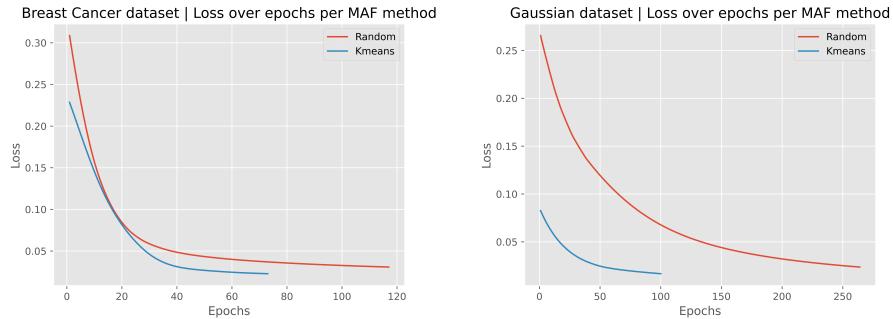

Figure 1: The figure demonstrates the benefits offered by MAF initialization, mainly decreased number of epochs and better starting point.

Table 3 deals with the speedup and predictive performance tradeoff.

Table 3: Ratios of accuracy, F1 score, and training time for Random and Confidence MAF initializations across datasets

Dataset	Accuracy Ratio	F1 Ratio	Training Time Speedup, x
Brain Tumor	1	1	1.13
Breast Cancer	1	1	1.14
Gaussian	1	1	2.47
Rectangle	1	1	1.62
Uniform	1	1	1.90

The results in Table 3 were rounded up to 2 digits. We can infer that accuracy and the f1 score remain unchanged while we experience a speedup of 1.65x.

3.2 Uncertainty Analysis

After the model has been trained, the question arises of how reliable the rules used by the model are. To determine this, we must examine the MAFs associated with these rules. In this subsection, we will describe the traditional definition of uncertainty, demonstrate its weaknesses, suggest an alternative definition, and analyze both traditional and newly suggested uncertainties for different MAF initialization methods.

3.2.1 A New Approach to Rule Importance Estimation

Traditionally, uncertainty has been defined by the mass of the complete set, with lower uncertainty indicating a more reliable rule. However, this is not always the best approach. Table 4 demonstrates an example.

Table 4: Illustration of the Pitfalls of the Traditional Approach

Rule	Mass First Class	Mass Second Class	Uncertainty	Ratio
1	0.49	0.51	0	1.04
2	0.01	0.09	0.9	9

Rule 1 shows zero uncertainty, which might seem ideal. But the nearly equal masses for the two classes make it hard for the algorithm to distinguish between them. On the flip side, Rule 2, despite its high uncertainty, has a significant difference in class masses (a ratio of 9), which enhances its ability to clearly separate the classes.

Given these insights, we propose a fresh approach that factors in both the uncertainty and the ratio between the most probable and second most probable masses.

Our method is inspired by the F1 score, which is the harmonic mean of precision and recall. To optimize our evaluation, we focus on maximizing the value of $1 - \text{uncertainty}$ and the class mass *ratio*. This approach allows us to prioritize both a high ratio and low uncertainty simultaneously. To unify these metrics into a single measure, we calculate their harmonic mean. However, since $1 - \text{uncertainty}$ ranges from 0 to 1 and the *ratio* can vary widely, we first normalize the *ratio* using min-max scaling across all rules before applying the harmonic mean. This scaling ensures that both metrics contribute equally to the final score. To put this formally

– **Uncertainty Adjustment:**

$$U' = 1 - U$$

where U is the original uncertainty.

– **Normalization of the Ratio:**

$$R' = \frac{R - \min(R)}{\max(R) - \min(R)}$$

where R is the original ratio (when dividing the values of two masses we add $\varepsilon = 0.01$ to denominator to avoid zero division error), and $\min(R)$ and $\max(R)$ are the minimum and maximum values of the ratio across all rules, respectively.

– **Harmonic Mean Calculation:**

$$H = \frac{2 \cdot U' \cdot R'}{U' + R'}$$

where U' is the adjusted uncertainty value and R' is the normalized ratio.

3.2.2 Experimental Results

Now we'll take a look at the effect of our new MAF initialization both based on traditional approach for importance calculation, and on newly proposed one. Below, we will define improvement as the ratio of *MED.Random* and *MED.Clustering*.

Table 5: Average and median uncertainties for Random and Clustering MAF initializations

Dataset	AVG. Clust.	AVG. Rand.	Med. Clust.	Med. Rand.	Improvement
Brain Tumor	0.258	0.713	0.246	0.732	2.979
Breast Cancer	0.314	0.710	0.262	0.703	2.685
Gaussian	0.225	0.330	0.229	0.302	1.318
Rectangle	0.201	0.448	0.203	0.434	2.135
Uniform	0.150	0.262	0.096	0.144	1.493

Table 5 shows that on average the clustering approach yields in uncertainty reduction by a factor of 2.12.

Table 6: Average and median newly defined uncertainties for Random and Clustering MAF initializations

Dataset	AVG. Clust.	AVG. Rand.	Med. Clust.	Med. Rand.	Improvement
Brain Tumor	0.247	0.313	0.075	0.336	4.471
Breast Cancer	0.156	0.359	0.075	0.411	5.486
Gaussian	0.633	0.625	0.807	0.757	0.937
Rectangle	0.473	0.536	0.457	0.571	1.249
Uniform	0.732	0.700	0.935	0.876	0.937

Table 6 shows that on average the clustering approach yields in uncertainty reduction (harmonic mean approach) by a factor of 2.61.

See below Figure 2 for an example of rule uncertainties for the Breast Cancer dataset [Wolberg and Mangasarian 1990].

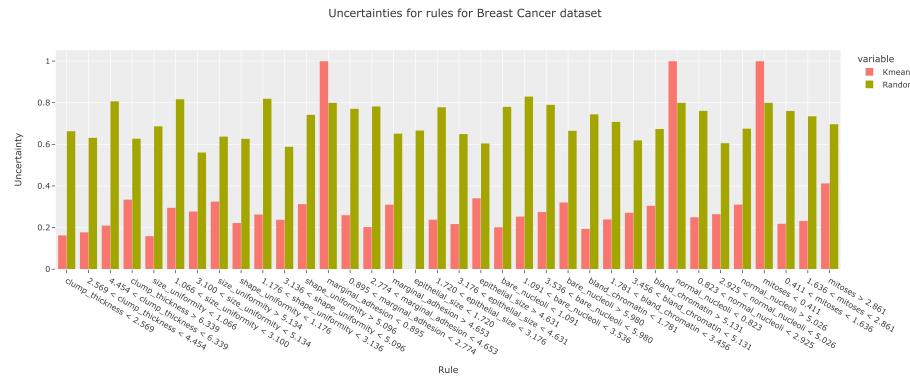

Figure 2: Uncertainties per rule for different MAF initialization methods

4 Conclusions and Future Work

We saw that by introducing the concept of *representativeness* for individual data points—and using it to guide clustering-based Mass Assignment Function (MAF) initialization—we achieved a $1.6\times$ reduction in training time for DSGD classifier. The proposed initialization method not only offers a more favorable starting point for optimization but also reduces the number of required epochs, all while preserving predictive performance equivalent to baseline method.

We further addressed the need for a more flexible definition of rule uncertainty by proposing a measure that takes into account the ratio of masses of singleton classes. Our MAF initialization approach reduced uncertainty by a factor of 2.6 using the newly proposed measure and by 2.1 using the traditional measure.

Future work may involve extending this approach to multi-label datasets, exploring additional clustering techniques, and leveraging the reduced training time to incorporate non-singleton classes or increase the number of generated rules.
